01 · CRONBACH'S ALPHA

internal consistency of one scale

Table 1. Reliability

ω	α	95% CI	N items	N cases
.63	.63	[0.56, 0.70]	3	301

Table 2. Item-total statistics

Item	Corrected item-total r	α if item dropped
x1	0.45	.51
x2	0.37	.61
x3	0.48	.46

Figure. Item contribution

Understanding the numbers

ω (omega). The headline reliability coefficient for this scale - it only assumes a one-factor (congeneric) model, so it's preferred over α when item loadings differ (McNeish, 2018). Here, $\omega = .63$, 95% CI [0.56, 0.70] - values $\geq .70$ are commonly considered acceptable, $\geq .80$ good, and $> .95$ may suggest item redundancy.

α (Cronbach's alpha). A secondary/legacy reliability coefficient that assumes every item loads equally (tau-equivalence); it is a lower bound on reliability when loadings differ. Here, $\alpha = .63$.

95% CI. The range likely to contain ω 's true value, given sampling variability. Here, the 95% CI for ω is [0.56, 0.70].

N items. The number of items making up this scale. Here, N items = 3.

N cases. The number of complete cases (participants) the estimates are based on. Here, N cases = 301.

Corrected item-total r. How strongly one item correlates with the sum of the remaining items - a diagnostic of whether it belongs on this scale. Each row is one item's own item-total correlation; a low or negative value flags an item that may not belong on this scale.

α if item dropped. What Cronbach's α would be if that one item were removed from the scale - it flags items worth reviewing. An item whose "alpha if item dropped" value is higher than the overall α (.63) is a candidate for review.

How to read this test

ω (McDonald's omega) is the headline reliability coefficient; it assumes only a congeneric (one-factor) model and is preferred over α when item loadings differ (McNeish, 2018). α (Cronbach's alpha) assumes tau-equivalence (equal loadings) and is a lower bound when loadings differ; it is retained as a secondary/legacy coefficient because reviewers still request it. Both range 0–1; $\geq .70$ is commonly considered acceptable, $\geq .80$ good, $> .95$ suggests item redundancy — treat these as heuristics, not pass/fail thresholds. The "alpha if item dropped" column flags items that, if removed, would raise α — candidates for review. A high coefficient does not prove unidimensionality.

APA template: Internal consistency was below the conventional .70 threshold, $\omega=.63$ (95% CI [0.56, 0.70]); Cronbach's $\alpha=.63$.

Statistical basis: Cronbach's alpha (tau-equivalent reliability) (Revelle W (2024). psych: Procedures for Psychological, Psychometric, and Personality Research. Northwestern University, Evanston.); McDonald's omega as the headline reliability coefficient (preferred over alpha when loadings differ) (McNeish, D. (2018). "Thanks coefficient alpha, we'll take it from here." Psychological Methods, 23(3), 412-433.). Full references in the exported CITATIONS.txt.
